Late Paleozoic A-type granite plutons were intruded along an active shear zone in the Cobequid Highlands of Nova Scotia. The majority of these granites host primary REE minerals, and contain evidence of several events of hydrothermal REE remobilization. Granites of the West Moose River Pluton, however, contain exclusively secondary REE minerals. The West Moose River Pluton is located in a stepover zone between two major late Devonian faults, and just north of the Carboniferous Cobequid fault. It intruded Horton Group rocks and has been dated at 361 ± 3.5 Ma (U-Pb on zircon). Small mafic dykes and sills in the area post-date the granite (ca. 334 Ma Ar/Ar on whole-rock, biotite), and some mineralogically resemble minette (biotite-rich lamprophyre). The minette dykes and sills contain mineralized veins of different relative age and mineralogy. Based on cross-cutting relationships, the types of veins from oldest to youngest include albite, chlorite and calcite-fluorite-filled fractures. Rare late pyrite-barite veins are also present. Re-opening of old fractures led to the formation of composite veins. The only REE mineral found in the minette dykes/sills is synchysite-(Ce) which occupies late cross-cutting veins. Remobilization of REE was enhanced by fluorine-carbon-rich fluids, which caused the simultaneous precipitation of fluorite, calcite, and synchysite-(Ce). The precipitation of synchysite-(Ce) in minette was governed by the interaction of REE-bearing fluids with the Cl-bearing biotite of the host-rock. This study underlines the importance of halogens during fluid-rock interactions for the precipitation of REE, and identifies minette dykes/sills as possibly important hosts of hydrothermal REE-minerals.
