

trict of southern Illinois are submarine erosion channels, in part triggered by faulting.

AUMENTO, F., Dalhousie University, Halifax, Nova Scotia, Canada

#### X-RAY STUDIES ON NOVA SCOTIA ZEOLITES

The more common zeolites from the Triassic basalts of Nova Scotia were studied by single crystal photography and diffractometry techniques. These included analcite, apophyllite, chabasite (including the variety "acadielite"), gmelinite, laumontite, mordenite, natrolite, stilbite, thomsonite, and other minerals occurring as intergrowths.

Buerger precession photos were taken and cell parameters calculated directly. These parameters were processed by an IBM 1620 electronic computer to calculate all possible lines and indices which could occur in the respective diffractograms. Results were compared with experimentally obtained diffractograms, and tabulations were made of actual "d" spacings so obtained against tentative indices. Cell parameters were then recalculated with greater precision from the indexed diffractograms.

A sequence of crystallization, related to the stratigraphy of the basalts, was tentatively formulated from field observations to be as follows: silica acting as a base, with chabasite and gmelinite as the first zeolites, followed by stilbite, heulandite, laumontite, apophyllite, analcite, thomsonite, and finally natrolite (with mesolite intergrowths).

#### MIDDLE TERTIARY FORAMINIFERAL PALEOECOLOGY, SAN JOAQUIN VALLEY, CALIFORNIA\*

A detailed study was made of the foraminiferal paleoecology of the Middle Tertiary of the San Joaquin Valley, California. General trends of use in paleoecology include: (1) increase of autohigenes away from shorelines, (2) progressive diversification of foraminiferal species and increase in foraminiferal abundance away from shore, and (3) concentration of planktonic species in the upper bathyal and outer shelf zones of marine basins. Bathymetry of modern homeomorphs of Tertiary species serves as the basis for establishing seven major biofacies for the California Tertiary, representing depths ranging from estuarine to deep bathyal conditions.

From Zemorrian to Luisian time, water depths in the San Joaquin marine basin were about 6,000 feet; in later Miocene time there was gradual shoaling, resulting in widespread shallow marine and paralic conditions in the Pliocene. Displaced faunas were most abundant near the base of steeper slopes of the reconstructed marine environments of the Middle Tertiary. Abyssal and shoal faunas appear to have longer geologic ranges, generally, than biofacies representing intermediate depths.

Paleotectonism was assessed in terms of vertical changes; changes amounted to many thousands of feet for each stage, especially in perimeter areas of the marine basin. Volumetric analyses suggest that about 900 cubic miles of subsidence occurred in the Zemorrian, with a progressive decrease to a minimum value of about 300 cubic miles in the Relizian, and increasing values for the remainder of the Miocene.

\* Publication authorized by the Gulf Oil Company of California.

More than 5,000 cubic miles of rock represent the marine sediment deposited in the San Joaquin basin during the middle Tertiary stages; more than 4,000 cubic miles of this were deposited in bathyal marine conditions, and most of the oil produced has come from these sediments. Oil fields occur in areas that have been active tectonically, near steeper bottom slopes of the reconstructed environment, and where there are rapid changes in biofacies.

#### ELECTRON MICROSCOPIC STUDIES OF PLANKTONIC FORAMINIFERA

The wall structures and surface features of several modern planktonic foraminiferal species were examined with an electron microscope for the purpose of evaluating the taxonomic and ecologic significance of such microstructural details.

Species belonging to spinose *Globigerinoides*, non-spinose *Globoquadrima*, and non-spinose *Globorotalia* were selected because they are three representative taxa among the planktonic Foraminifera.

Surface replicas were made using the Triafol method, which has been found superior to direct shadowing and Polystyrene techniques. Photographs have been taken stepwise from low magnifications with the light microscope to higher magnification electron micrographs in stereo pairs.

In the juvenile stages when the individuals live near the ocean surface, the test wall is thin and transparent and is composed of small calcite crystals with their c- and major growth axes normal to the shell surface. In the later stages when the organisms descend to lower water depths there is additional crystal growth in the form of a calcite crust producing columnar prisms whose free ends are rhombic pyramids. As some of the prisms increase in size, other prisms are squeezed out by differential growth; the rhombic pyramids are especially well developed along the keel and apertural side of *Globorotalia menardii* and *G. truncatulinoides*.

Transitional steps in the test thickening of *G. sacculifer* have been observed from specimens having large, open pores and distinct spine bases to specimens having constricted pores, obscure spine bases, and surficial encrustment of calcite crystals.

Distinguishing between variations in primary test features (e.g., keel, pores, apertural lip) and those due to developmental phases as observed with the electron microscope is complicated by variations due to environmental influences.

#### DISTRIBUTION AND MORPHOLOGICAL VARIATIONS OF LIVING PLANKTONIC FORAMINIFERS

Surface (0-10m) and vertical (300-0m) plankton samples were collected at seventy stations (116 samples) in the North Atlantic during the summer of 1962. Three faunal provinces were recognized. The subarctic fauna consisted of *Globigerina bulloides*, *G. quinqueloba*, and *G. pachyderma*. The subtropical fauna was typified by *Globigerinoides ruber* and *G. sacculifer*. The subarctic-temperate boundary was crossed five times in the western half of the northern traverse from New York to Scotland. The temperate fauna was dominated by

*Globorotalia inflata* (d'Orbigny) but also included sub-arctic or subtropical species. Highest foraminiferal concentrations were found in the temperate-subarctic zone, and the lowest in the central Sargasso Sea.

Bathythermograph temperatures ranged from 4.4°C. to 27.5°C. Temperature inversions occurred at nine stations SE. of Newfoundland. Within the BT range (0-274 m) temperatures fluctuated from 2.2°C. to 10.6°C. Surface salinities varied from 32.58 ‰ in cold water to 37.59 ‰ in warm water.

Morphological variations resulting from environmental influences were evident in some species. The maximum diameter of *Globigerina bulloides* was generally less than 0.4 mm above 14°C. Large specimens (0.6+mm) and specimens with the aperture over four chambers were abundant below 12°C. and when the salinity was less than 35.5 ‰. Deeper-water samples from stations having temperature inversions contained abundant forms with a reduced final chamber, similar to *Globigerina quadrilata* Galloway and Wissler. The terminal chamber in some specimens had a secondary aperture.

*Globigerina* cf. *quinqueloba*, common in waters below 15°C., graded into *G. pachyderma* with decreasing temperature. Typical *G. pachyderma* was not found in surface tows. Although encountered rarely, it did appear when water temperatures were below 10°C.

*Globorotalia inflata* was abundant between 13.5°C. and 18°C. Only deep-water tows with temperatures about 10°C. contained small forms with thick tests, a reduced final chamber, and an aberrant aperture.

The signal morphological variation was observed from the deepest tow taken (0-1150 m), and contained forms transitional between common *Hastigerina pelagica* and large, digitate *Hastigerinella rhumbleri*.

That depth and temperature greatly influence the distribution as well as the morphology of planktonic foraminifers is evident.

BEALES, F. W., University of Toronto, Toronto, Ontario, Canada

#### DIAGENESIS IN PELLETED LIMESTONES

The abundant pelleted limestones encountered in the geologic record are of polygenetic origin. Selected examples, biased by the author's personal field experience, are used to illustrate various textures and structures involving different pellet and matrix types.

Lithification is the most important problem. A remarkable lack of features apparently due to compaction characterizes all pellet limestones. Volume reduction by stylolitization is common, but the basic limestone fabric remains intact and essentially uncompressed. Apart from stylolitization which appears to be a late stage diagenetic effect, detectable pressure solution at points of grain contact is minor.

Calcite filling of apparent voids raises the question of what constituted a void? It is suggested that more stable crystals could grow equally as well in "voids" largely filled by metastable crystals as in fluid-filled space and the source problem is lessened. The presence of sparry or fibrous calcite is not necessarily evidence of a pre-existing void.

Drop in relative sea-level and exposure to fresh water probably promoted lithification but they were not the prime control. The course of lithification depended more on the primary distribution of carbonate minerals, particularly aragonite.

Dolomitization and silicification are only to be mentioned from the point of view of their bearing on lithification and the development of porosity.

BELYEA, H. R., Geological Survey of Canada, Calgary, Alberta, Canada

#### DIAGENESIS AND DEPOSITIONAL ENVIRONMENT OF PRE-HARROGATE DEVONIAN, BRITISH COLUMBIA\*

The Middle Devonian of the Stanford Range, British Columbia, is separated into a lower, gray, light gray, and locally red-weathering sandy limestone, dolomite, and sandstone formation laterally equivalent to the Burnais gypsum and an upper fossiliferous brown limestone and dolomite, the Harrogate formation, both of which are described by Belyea and Norford (in press).

The lower formation consists predominantly of cryptocrystalline silty to sandy limestone, dolomite, sandstone, and breccias. Beds 2 inches to 2 feet thick are separated by undulatory surfaces, locally channelled. The carbonates were probably deposited as ooze, some of the dolomite being primary or early diagenetic. Post-depositional changes include micro-brecciation, slump structures, burrowing in plastic carbonate, and desiccation cracks filled by calcite or hematite. Advancing dolomitization is marked by growth of euhedral rhombs, commonly with a nucleus of dusty material, pyrite, or spores. Increase in number and size of rhombs results in a crystalline grain growth mosaic. Pellets, bahamiths, detrital grains, and older fabrics are partly or completely destroyed in the process. Internal cavities and fractures are filled by crystalline (granular) cement and drusy growth. Quartz grains are extensively corroded by carbonate, and late tension cracks are filled by quartz and carbonate. Ostracods and charaphytes are common in some beds. This rock unit, correlative with the Burnais gypsum, is interpreted as the deposit of a shallow water, near-shore environment, periodically exposed, that received drainage from an early Paleozoic terrane of carbonates and clastics.

The overlying Harrogate is dark brown, mostly aphanitic, limestone and finely crystalline dolomite. Post-depositional effects have resulted in development of grain-growth mosaic and drusy growth. Deposition took place in deeper water than the lower unit but subject to wave or current action; lack of oxidation due to abundance of organic growth is suggested as the cause of dark color.

BEAVER, HAROLD H., Humble Oil and Refining Company, Houston, Texas

#### DIFFERENTIATION OF LATE MISSISSIPPIAN—EARLY PENNSYLVANIAN PENTREMITES

Blastoids were virtually unknown in post-Mississippian rocks of North America until about 50 years ago when abundantly occurring specimens of *Pentremites* were described from Morrow beds in Oklahoma and Arkansas. The early Pennsylvanian age of these beds has been generally accepted by geologists for many years; some paleontologists, however, have questioned this age assignment because of the gross resemblance of type Morrow *Pentremites* to those of the upper Mississippian Chester. Morrowan *Pentremites* can be differentiated from those of the late Mississippian by a distinctive external shape and ambulacral cross-sectional outline and, internally, by the hydrospires which have a characteristic shape, thick walls, and a nearly constant number of hydrosphere folds, except for a reduced number of folds adjacent to the anus. In the field, latest Chester *Pentremites* commonly can be distinguished from those
